Abstract: Diabetic foot complications remain major medical, social, economic problems that are seen in all types of diabetes in every country however, the reported frequencies of amputation and ulceration vary considerably as a consequence of different diagnostic criteria used.

Aim: To study the etiology, presentation, and the management of diabetic foot ulcer to study the prognostic factors of diabetic foot in relation to plan of treatment. To increase the meagre awareness of diabetic foot problems. To understand the role of various factors involved in the complications arising out of diabetic foot and ascertain their role in the prognosis in relation to the plan of treatment. To reduce the risk of lower limb complications in people with diabetes. To empower diabetics in better foot care, early problem detection and in seeking timely help.

Material and Methods: In this case study 75 patients were studied. This study was conducted from December 2013 to September 2015. The protocol for the study was approved both by the Department Of General Surgery and the Ethical Review Committee of Meenakshi Medical College Hospital and Research Institute, Kanchipuram.

Results: Findings were tabulated according to age and other clinical aspects.

Conclusion: Age, gender, duration of diabetes, mode of treatment of diabetes and tobacco smoking did influence whether or not a diabetic with a foot lesion will have major amputation, an unsatisfactory outcome of primary treatment, prolonged hospital stay or will die. Also, the presence of foot infections alone, microangiopathy (nephropathy, retinopathy), foot ischaemia alone or neuropathy alone had no relationship to poor prognostic indices. In addition, dyslipidemia, hypertension and infection of the foot were related to need for major amputation. The factors that influence the outcome seem to be male gender, delay of management, quality of medical treatment, surgical attitude, inadequate level of amputation and finally lack of structured prevention. We therefore suggest that the high morbidity seen with diabetic foot lesions could be reduced by optimizing glycaemic control, using combination antibiotic chemotherapy, vigorously correcting anaemia and encouraging early presentation of even mild lesions before underlying bone disease supervenes. Prevention is based on the patient's education, general practitioners' training and a better and more efficient cooperation between surgeons and diabetologists.

I. Introduction

Diabetic foot complications remain major medical, social, economic problems that are seen in all types of diabetes in every country however, the reported frequencies of amputation and ulceration vary considerably as a consequence of different diagnostic criteria used. Among the many chronic complications of diabetes, diabetic foot has remained the most feared complication, with both patients and treating health care professionals sharing the dread in equal measure. Major challenges remain in getting across important messages relating to the diabetic foot:

- a. Foot ulceration is common, affecting up to 25% of patients with diabetes during their lifetime.
- b. Over 85% of lower limb amputations are preceded by foot ulcers and diabetes remains the most common cause of non-traumatic amputation.
- c. Prevention is the first step towards solving diabetic foot problems. It is estimated that a leg is lost to diabetes somewhere in the world every 30 seconds; a more important fact is that up to 85% of all amputations in diabetes should be preventable.
- d. Reduction in amputations will only be achieved if health care professionals from all specialties realize that, as Brand once stated, "pain is God's greatest gift to mankind": it is the loss of pain that permits patients with neuropathy to develop ulcers and continue walking on them despite the presence of often over-whelming infection.

- e. Strategies aimed at preventing foot ulcers are cost-effective and can even be cost saving if increased education and effort are focused on those patients with recognized risk factors for the development of foot problems.
- f. Diabetes is now the most common cause of Charcot neuroarthropathy another condition that should be preventable.

II. Aim And Objectives

To study the etiology, presentation, and the management of diabetic foot ulcers.

To study the prognostic factors of diabetic foot in relation to plan of treatment.

To increase the meagre awareness of diabetic foot problems.

To understand the role of various factors involved in the complications arising out of diabetic foot and ascertain their role in the prognosis in relation to the plan of treatment.

To reduce the risk of lower limb complications in people with diabetes.

To empower diabetics in better foot care, early problem detection and in seeking timely help.

III. Material And Methods

A total of 100 patients with diabetes mellitus from inpatients and outpatients were screened by meticulous clinical examination, especially inspection and palpation for diabetic foot ulcer. Seventy Five of the total number screened satisfied the inclusion criteria for the study. Diabetic foot ulcers was operationally defined as a breach on the normal skin occurring as induration, ulceration or change of colour on the foot for duration equal to or more than one week. Only patients with active foot ulceration(s) were included in the study.

For each of the recruited subjects, a history was obtained and it detailed the patient's demographics including the age, gender, and marital status. Smoking, alcohol use, occupation, presence of trauma at onset of ulcer was noted. History regarding the diabetes including duration of disease (estimated from year of diagnosis), and the mode of treatment from either the patient or available hospital records were documented. The presence of neuropathic pain was noted.

A physical examination was then performed. Height, weight, Blood Pressured was recorded. Both feet were examined and the site, state and the stage of foot ulcers were documented. The presences of the high risk non-ulcer lesions were also described. The lesions were staged based on the Meggitt-Wegner classification.

Peripheral neuropathy was assessed by elucidating the presence or absence of vibration sense using the 128Hz tuning fork on the medial and lateral malleoli and documented. The pressure sensation was done. Then neurological disability scoring (NDS) system was used to each foot. In a situation where prior foot amputation had been performed, the score awarded to the examined foot was doubled.

Range of neuropathy score: 0 – 10

- 0 – 2 = No neuropathy
- 3 – 5 = Mild neuropathy
- 5 – 8 = Moderate Neuropathy
- >9 = Severe Neuropathy

Peripheral vascular disease: The dorsalispedis and posterior tibial arterial pulses were palpated with the patient in supine position and graded as present or absent. Lower limb Arterial Doppler study had been done in the patients at time of inclusion and re-visit.

The other dermatological and/or high risk lesions looked for were dryness, cracks, fissures, ingrown and/or improperly trimmed nails, edema, foot deformities e.g. Charcot joints, hammer toes, pascavus and/or corns. X-rays were done to stage the ulcers of the patients.

Using the clinical information obtained, the type of the foot lesion was determined and classified as neuropathic, ischaemic or neuroischaemic. Foot ulcers were categorized as ischaemic when peripheral vascular disease was present but the neurologic disability was less than or equal to 2 ; neuropathic when there was neurological disability more than or equal to 3 but no obvious peripheral vascular disease and neuroischaemic when both neurological disability and evidence of peripheral vascular disease were present.

After the history and full clinical assessment of the patients in fasted state for about 10 hours, venous blood drawn and sent for fasting blood sugars and lipid assays. Also blood was sent for glycosylated hemoglobin (HbA1c) values. The results were then reported in percentage as per assay test recommendation as:

HbA1c ≤ 7% - good metabolic control

>7 to <10% - fair control

≥10% - poor metabolic control.

A pus swab was obtained from the ulcers and was delivered to the lab within half an hour. The data was summarized in tabular form and is presented in the form of diagrams, tables, bar charts and histogram as appropriate. Qualitative data were entered in form of percentages and where appropriate associations were made.

IV. Observations And Results

A study was undertaken in seventy five patients of diabetic foot in Meenakshi Medical College And Research Institute, Enathur, Kancheepuram during December 2013 to September 2015. The observations are as follows:

Table -1: Age Distribution

Peak age incidence was found to be sixth decade. But the diabetic complications were more common in the fifth decade in the males and sixth decade in the females.

| AgeGroup | Frequency | Percentage |
|--------------|-----------|-------------|
| 30-39 | 4 | 5.3% |
| 40-49 | 12 | 16.0% |
| 50-59 | 37 | 49.3% |
| >60 | 22 | 29.3% |
| Total | 75 | 100% |

Table 1a: Age Group *Procedure

V. Discussion

The study was conducted in Meenakshi Medical College, Kanchipuram, TamilNadu. The figures are comparable to other studies, but if the differences are significant, this is due to a regional variation in prevalence of diabetes mellitus and the local operating risk factors of diabetic foot ulcer disease.

The mean age of patients with diabetes was found to be 55 years. Peak age of incidence of diabetic ulcers was 51 – 60 years. Margueritte et al²⁶ in Seattle, USA, found a comparable mean of 60 years and a study done by P.N.Nyamu³¹ et al in Kenyatta National Hospital, Nairobi, found a mean age of incidence as 56.9 years. This comparable mean age may suggest certain time – dependent risk factors in the evolution and course of diabetic foot ulcer disease which are common to diabetes in whatever environment. Age of onset of diabetes is also different in continents.

Men with diabetes are more likely to suffer amputation than women. According to Gayle E. Reiber et al¹⁶ a consistently higher ulcer rate was found in males than in females. The estimated amputation rate in diabetic subjects is higher for males than for females. This is a uniform finding in most U.S. hospital discharge studies, with 1.4-2.7 times excess risk for males compared with females^{2,17}. In 1990, the age-adjusted amputation rate for diabetes, computed from NHDS and NHIS data, was 61% higher in males than females (10.3 per 1,000 versus 6.4 per 1,000)³³. This amputation risk was more pronounced in younger males. In our study, the male to female

ratio is 3.1 : 1 approximately and the prognosis is worse in male of age more than 50 years and in females more than 45 years.

The mean duration of diabetes in this study is 10.52 years comparable to 7.98 years, 13 years and 5 years in Margueritte et al²⁶ in Seattle, USA study, P.N.Nyamu³¹ et al in Kenyatta National Hospital, Nairobi study, McLigeyo and Otieno's study on diabetic foot ulcers²⁷ respectively. The variation in results may be due to difference in quality of diabetes care at various centres. Better diabetes care can prolong the onset of ulceration. This study revealed that the longer the duration of diabetes, the higher the risk of occurrence of infection and amputation. This is in correlation with study conducted by Nelson RG, Gohdes DM²⁷. There is an increased association with atherosclerosis, peripheral neuritis in patients with longer duration of diabetes and poor glycaemic control.

Hypertension is a risk factor in the disease process of diabetic foot ulceration. Control of hypertension has been well shown to reduce cardiovascular mortality. In our study, 30 out of 50 patients who were hypertensive have undergone amputation and hence it can be regarded as a poor prognostic factor. In a study conducted by Ogbuawa et al³⁰, they found hypertension to be an independent risk factor for macrovascular disease and subsequent foot ulceration. A lot of other studies conducted previously had conflicting results with some failing to show any association between blood pressure and diabetic foot ulcers^{17,29,13}. In accord with the haemodynamic hypothesis early hyperaemia and capillary hypertension promote more sinister late functional abnormalities with increasing duration of diabetes. These late functional abnormalities include loss of autoregulation and reduced hyperaemic responses which interact with loss of neurogenic flow regulation, disturbed endothelial function, and abnormal rheology to produce the familiar clinical picture of the diabetic foot². Both essential hypertension and diabetes mellitus affect the same major target organs. The common denominator of hypertensive/diabetic target organ-disease is the vascular tree. As it can be seen that both the systemic diseases affect the vascular tree the patients with diabetic foot ulcer would have poor wound healing. The Framingham study suggests that smoking in diabetic foot patients, at least, has the same adverse effect on macrovascular disease as they do in non-diabetics. In my study, 42 out of 75 patients gave the history of smoking in whom higher levels of amputations were attempted with poor prognosis. Smoking affects the small blood vessels and make the wounds heal slower.

In the observation of wound healing rates with high HbA1c, it was observed that patients with low HbA1c values had faster healing. My study shows 32 patients had high HbA1c of which 72.9% showed poor wound healing rates and underwent subsequent amputation. This is in correlation with Andrea L. Christman et al³ study which showed that individuals with HbA1c of 5.6% had a wound healing rate of 0.35 cm² per day whereas those with HbA1c 11.1% had a healing rate of 0.001 cm² per day. This suggests that a relationship exists between faster wound healing rate and low HbA1c levels. Many physiological factors that are thought to contribute to poor wound healing in diabetic foot individuals include decreased or impaired keratinocyte and fibroblast migration and proliferation, cytokine and growth factor function, and angiogenic response, and response to infection⁷. Many of these mechanisms involve hyperglycemia. Hyperglycemia reduces keratinocyte migration and proliferation^{22,37}. Also it adds to the oxidative stress with the production of reactive oxygen species²⁰. In my study, of the 23 out of 32 patients who underwent amputation, 3 cases underwent forefoot amputation, 7 underwent below knee amputation, 1 underwent above knee amputation, 12 underwent toe amputations.

In my study, dyslipidemia in diabetic foot patients is found to be a poor prognostic factor as it delayed wound healing significantly. Dyslipidemia directly did not influence the diabetic foot as such but it played an important role in the development of peripheral vascular disease which in turn affected the outcome of diabetic foot. This finding is in correlation with a study done by P.J. Palumbo et al⁹, where they found that age, sex, diabetes, hyperlipidemia, hypertension, and cigarette smoking are significant risk factors for LEAD. In patients with diabetes, vascular disease, ABI, current smoking, and arm systolic blood pressure were identified as significant independent risk factors for LEAD.

Several analytic studies have provided evidence for an association between neuropathy and lower extremity amputations. In the cohort study of Pima Indians⁴³ and in the Seattle VA case-control study⁵ it is observed that impaired vibratory perception was a statistically significant risk factor for amputation after controlling for age, sex, and diabetes duration. In the latter, the significance of this predisposing condition in terms of population-attributable risk percent was high because of the higher prevalence of hypoesthesia among cases (78%) than among controls (18%). Foot sensory neuropathy emerged as the most predictive of foot ulcer risk in our population. Several case-control and prospective studies have demonstrated higher foot ulcer risk in association with insensitivity to the 5.07 monofilament, absent Achilles tendon reflex, and diminished vibration sensation as reflected by a hallux vibration perception threshold .25 measured using the biothesiometer (22–24). In our study, patients

According to a study conducted by Robert J. Hinchliffe et al³⁸, they concluded that both peripheral neuropathy and peripheral arterial disease predispose to the development of ulcers and to their slow healing.

Neuropathy inhibits healing partly by increasing forces on certain parts of the foot while walking (as a result of motor neuropathy and wasting of the small muscles of the foot) and by a loss of protective behaviour (as a result of reduced sensation). Peripheral arterial disease inhibits healing through its impact on local blood flow and a disruption of the processes needed for re-epithelialization. In another study conducted by Robert G. Frykberg et al⁹, it has been concluded that peripheral arterial disease (PAD) rarely leads to foot ulcerations directly. However, once ulceration develops, arterial insufficiency will result in prolonged healing, imparting an elevated risk of amputation. Additionally, attempts to resolve any infection will be impaired due to lack of oxygenation and difficulty in delivering antibiotics to the infection site. Therefore, early recognition and aggressive treatment of lower extremity ischemia are vital to lower limb salvage. In my study it has been found a major percentage of patients with associated peripheral vascular disease had undergone amputation.

Wagner's classification score may be different for a surgeon as compared to physician because the diabetic foot patients come with advanced disease to a surgeon and for this reason patients with grade 0, 1, 2 are lesser and those with grade 3, 4, 5 are more in our study. The standard treatment for diabetic foot according to Wagner's classification is prevention for grade 0, antibiotics and good glycemic control for grade 1. In grade 2 patients need hospitalization, as they need surgical intervention along with antibiotics and glycemic control. Grade 3 requires debridement and some sort of amputation. In grade 4, aggressive debridement and amputation while in grade 5 the preferred treatment is below knee amputation. Initial aggressive and radical debridement with daily surgical follow-up is the mainstay in the treatment of diabetic ulcers in nearly 90% of our patients. Patients with Grade 3, 4, 5 underwent amputation indicating grade of ulcer at presentation is a predictive factor for plan of treatment.

VI. Conclusion

Age, gender, duration of diabetes, mode of treatment of diabetes and tobacco smoking did influence whether or not a diabetic with a foot lesion will have major amputation, an unsatisfactory outcome of primary treatment, prolonged hospital stay or will die.

Also, the presence of foot infections alone, microangiopathy (nephropathy, retinopathy), foot ischaemia alone or neuropathy alone had no relationship to poor prognostic indices.

However, when these complications appeared in concert (neuropathy, ischaemia and infection) and when, at presentation, there was associated systemic disease (as shown by anaemia and leucocytosis), severe fasting hyperglycaemia, evident bone destruction and anaerobic superinfection, the outcome of treatment was adverse.

In addition, dyslipidemia, hypertension and infection of the foot were related to need for major amputation. Poor long-term control did influence prognosis adversely.

The factors that influence the outcome seem to be: male gender, delay of management, quality of medical treatment, surgical attitude, inadequate level of amputation and finally lack of structured prevention.

We therefore suggest that the high morbidity seen with diabetic foot lesions could be reduced by optimizing glycaemic control, using combination antibiotic chemotherapy, vigorously correcting anaemia and encouraging early presentation of even mild lesions before underlying bone disease supervenes.

Prevention is based on the patient's education, general practitioners' training and a better and more efficient cooperation between surgeons and diabetologists.
