Abstract: Avascular Necrosis (AVN) of the bone, aseptic necrosis and ischemic bone necrosis, is a relatively common disease characterized by death of the cellular elements of bone and marrow due to the interruption of the blood supply. Patients tend to suffer from post surgical pain, limitation of motion with stumbling gait along with aggravating of pain, numbness & spasm in gluteal region. This condition has a number of characteristics clinical and radiographic signs that differentiate it from other osteonecrotic conditions. ‘Mitchell’s GRADE A’ with marrow edema in head & neck regions of femur being the first characteristics of diagnostic feature. This is a case report of single post surgical issue with history of severe pain and difficulty in walking.

I. Introduction

Avascular Necrosis of the bone, also known as Osteonecrosis, aseptic necrosis and ischemic bone necrosis, is a relatively common disease characterized by death of the cellular elements of bone and marrow due to interruption of the blood supply. Most individuals who develop AVN are between ages of 20 and 50 years. The hip (femoral head) is the most commonly affected sites for clinically significant avascular necrosis.Osteonecrosis of femoral head is a devastating disease which often leads to the destruction of the hip. It is employed only in early stages of arthritis and its results are still of controversial efficacy and most of patients ultimately require total hip arthroplasty. Patients present with severe pain, gluteal region spasm and numbness with difficulty in walking. Recognition of these condition signs are important in order to make the post operative care and prevent possible complications.

II. Case Report

We report a case of 65 year old male with surgical procedure [Uncemented right & left total hip replacement] for arthritis of both hips secondary to avascular necrosis of femur head. He also provided a history of multiple surgical procedure for spine like lumbar discectomy, arthritis of knee earlier, including necrosis of both femoral head’s with marrow edema in head & neck regions of left femur and acetabulum. On Clinical examination, the patient demonstrated dysmorphic features with short range of movement and proportionally shorter right limbs. He had a large dense mass of bone with limitation of movement in the back of the spine. MRI of spine investigation revealed arthritis of both hips secondary to avascular necrosis of femur head and S/P L4-L5 Microdiscectomy bilateral core decompression. Lower extremities shows dryness of skin and swelling of both legs.The patient was subjected to special tests like Thomas test shows negative; Trendelenberg test couldn’t be done due to severe of pain, teleoscopy becomes negative and others are like relation, shoemaker’s line normal. Femur radiographs showed suggestive of avascular necrosis of both femoral heads [MITCHELL’S GRADE A] as described with marrow edema in head & neck regions of left femur and left acetabulum (Fig 1A).The(Fig 1B)Both femorals heads shows osteonecrotic changes.

FIG 2. Post Surgical X-rays shows artificial uncremented 32mm biolox delta ceramic femoral head (+5) size was Implanted.

III. Discussion
Osteonecrosis of the hip is characterized pathophysiologically by ischemia of bone marrow and eventual death of trabecular bone. The key of successful maintenance of hip osteonecrosis is early treatment, prior to onset of subchondral fracture and cartilage damage. Approximately, 5%-18% of all hip arthroplasties are completed on patients with a primary diagnosis. During diagnostic classification of osteonecrosistic medial thigh or groin pain with limitation of hip motion in patient’s less than 50 years of age should raise the suspicion of osteonecrosis. Patients usually present with slow onset, insidious groin pain that may be unilateral or bilateral. Symptoms are generally amplified with weight bearing and relieving by rest. The pain may also be in gluteal region, kness, or anterior and lateral thigh. Range of motion becomes limited, particularly hip abduction and internal rotation and logrolling elicits pain. Early stages of this disease can be often asymptomatic, and some patients present after articular surface collapse has already occurred. Hip prognosis can be significantly improved with early diagnosis, before articular collapse.

Other potential etiologies for osteonecrosis include childhood history of slipped capital femoral epiphysis (SCFE), deep sea diving or other hyperbaric conditions, SLE and other connective tissue disorders, fat embolus syndrome, gout and metabolic bone disease. The diagnosis is primarily based on the aforementioned radiographic features (Pre & Post Surgery). Fig 2. However, a post operative rehabilitation [Physiotherapy and Naturopathy] remains the gold standard treatment with longer duration of passive movement for duration of 15-20 minutes daily. Majority of the soft tissue heals in the first 12 weeks after surgery with minimal passive movements for total hip and legs (Table 1.1.1). Specific treatment options with supportive measures, prevention and management consisting the most important aspects of clinical care for the pain and disability from the arthritis influencing the quality of life and daily activities.

IV. Conclusion
Osteonecrosis is a pathology commonly seen in adults, in which collapse of femoral head and early onset of osteoarthritis may eventually necessitate a hip arthroplasty when non-operative measures. Basic science research to understand the pathophysiology and to develop therapies that can be translated to clinical application has progressed rapidly. Similarly, modern technologies improvements in surgical treatment methods have also improved outcomes over the past two decades and will continue to help the patient recover from this functionally debilitating joint disease. The importance of recognition of these features in the diagnosis and prevention of future complications is stressed in this case report with integrated approach.
