Abstract: The solitary fibrous tumor (SFT) is a rare soft tissue tumor that most commonly occurs in the pleura cavity. However, it has also been described in other sites of the body. A limited number of SFTs cases have been reported in the soft tissues of the oral cavity. The diagnosis depends on microscopic and immunohistochemical features, although imaging may help. Since this tumor shares a number of similar features with other mesenchymal lesions, the histological diagnosis of SFT may present with difficulties. Close follow-up over several years is recommended due to potential late local recurrence. We present, as we believe, the first case of an endosteal SFT, arising in the mandible.

Keywords: Solitary fibrous tumor; Oral cavity; Mandible

I. Introduction

Solitary fibrous tumors (SFTs) were firstly reported in the pleura by Klemperer and Rabin1 in 1931. These tumors are rare and most commonly arise in the thoracic cavity2. Most of them occur as slow-growing painless masses. Rarely, larger tumors may be a source of paraneoplastic syndromes such as hypoglycemia owing to the production of insulin-like growth factor3,4. SFT is a mesenchymal neoplasm, previously nomenclatured as localized benign mesothelioma, submesothelioma, or localized fibrous tumor of the pleura5. It is now recognized that this may also occur in extrapleural sites. Recently, however, SFT has been shown to originate from ubiquitous interstitial stem cells in various human tissues and its histopathological criteria have been established by the aid of immunohistochemistry6. SFTs arising in the soft tissue of the head and neck account for approximately 10% of all cases7. Those occurring in the oral cavity account for 3% of all head and neck cases8. In the present report we describe the occurrence of a SFT case in the angle region of the mandible. This is the first case report of a SFT arising in the mandible.

Case report

A 71-year-old Caucasian male patient attended the outpatient department complaining of a swelling in his left lower jaw. The mass was painless and noticed by the patient 5 months ago. Extraoral examination showed a slight fullness of his lower left face. Clinically there was no cervical lymphadenopathy. Hypoesthesia was evident in the region of distribution of the left inferior alveolar nerve. Intraorally, the lesion, firm in palpation, occupied the mandible from the first molar to the ascending ramus, expanding the buccal and lingual plates. The swelling was covered by healthy mucosa. The Orthopantomogram revealed a diffuse, poorly demarcated endosteous lesion in the region of the left mandibular angle (Fig.1). The computed tomography scan (CT) depicted an endosteal destructive lesion, measured 4.4 x 3.4 cm, causing expansion of the left mandible in all directions, destruction of both plates and lingual extraosseous extension (Fig.2). A Fine Needle Aspiration Cytology of the lesion was performed, showing malignant features, yet not specified otherwise. An incisional biopsy followed. The histopathology report indicated either a low grade osteosarcoma or a solitary fibrous tumor with malignant component. The distant metastases work up was negative. The patient under general anesthesia underwent a segmental mandibulectomy via a submandibular approach. The adjacent soft tissues were resected in clinically healthy tissues. The mandible was reconstructive using a 13-hole titanium plate. The postoperative period was uneventful. The patient had been examined regularly on an outpatient basis for one and a half year. At that time there was no clinical evidence of tumor recurrence and a CT scan was negative for findings. Unfortunately, thereafter the patient failed to attend the outpatient clinic.

Histological findings

The tumor consisted of spindle cells arranged in fascicles, short whorls or diffusely. The cells demonstrate moderate atypia and the mitotic range was 4 mitoses / 10 high power fields. In some areas the cells grow around dilated vessels showing a hemangioepicytomatoid pattern. There were no necrotic areas. Additionally, reactive bone production was also seen, especially at the periphery of the lesion. The lesion was also infiltrating the pre-existing mandibular bone, expanding into the surrounding tissues. Immunohistochemically the tumor cells showed strong positivity against Vimentin, CD34, CD99 and Bcl-2 (Fig.4).
II. Discussion

SFTs are uncommon spindle cell neoplasms of mesenchymal origin. Over 50% of these tumors are located in the thoracic cavity, but extrathoracic tumors have been reported in many sites including the liver, adrenal gland, skin, head and neck etc. In the head and neck, the most commonly affected site is the oral cavity. The most prevalent site is the buccal mucosa followed by the tongue and the lower lip. Cases have been also documented in the orbit, nose and paranasal sinuses, parapharyngeal space, larynx, major salivary glands and thyroid gland. The association of SFTs with the oral cavity, particularly the buccal mucosa, has led to the suggestion that SFT may be associated with trauma. The histopathogenesis of SFT is still controversial. Recent studies have indicated a mesenchymal origin rather than a mesothelial one, which was originally postulated. If SFTs originate from immature mesenchymal cells with pluripotential differentiation, they can arise in any mesenchymal tissue of the body including the oral cavity. SFT originating in bone and especially in the mandible has not been previously documented. To our knowledge, this is the first case of SFT arising in the mandible as an intraosseous lesion and spreading to the surrounding tissue, published in the English language literature. On CT the main characteristics were the osteolysis and the extension to the adjacent tissues. The spreading pattern clearly indicates that the tumor was originally located within the mandible. Although such kind of tumors may present with other systemic symptoms, some cases are incidental radiological findings.

There are no absolute distinctive diagnostic imaging features. Certain radiographic characteristics may be suggestive and should alert the inclusion of the SFT in the differential diagnosis. The most prominent feature of SFTs on CT and MRI, is that of a well-defined, isodense densely enhancing lesion. Regressive remodeling of adjacent bone is the most common radiographic osseous finding, since most SFTs are benign and slow growing lesions. Nevertheless, the presence of obvious bone destruction is generally associated with more aggressive tumors and the possibility of malignancy should be considered, although this is not always the case. It has been reported that diagnosis can be aided by fine-needle aspiration cytology. This is not supported by the literature and certainly does not apply in the case under discussion. As SFTs, hemangiopericytomas also stain positive for CD34. Some authors report that the presence of a basement membrane in hemangiopericytomas also allows them to be distinguished from SFTs. However, it is now generally accepted that the determination of hemangiopericytomas as a separate entity from SFTs may become obsolete because of their histopathologic features, which highly resemble cellular areas of SFTs.

The fourth edition of the WHO Classification of Tumours of Soft Tissue and Bone, published in 2013, classifies SFT and malignant SFT, as intermediate (rarely metastasizing) lesions. The term hemangiopericytoma is abandoned, used only to describe pattern of morphology. The clinical and histological diagnosis of an SFT may present difficulties in distinguishing this entity from other spindle-cell tumors. Immunohistochemistry helps in the distinction of SFTs from other soft tissue sarcomas including synovial sarcoma, benign fibrous histiocytoma, dermatofibrosarcoma protuberans, myofibroma, fibroma, and neurogenic tumors. CD34 is a marker for healthy endothelium and has been found to stain primitive mesenchymal stromal cells and several mesenchymal tumors. All malignant SFTs and 77% of benign SFTs stained positive for CD34 in one study. Therefore, the expression of conventional immunohistochemical markers such as vimentin, CD34, and CD99 might be important in the differential diagnosis of SFT from other spindle cell neoplasms. The absence of S-100 protein is essential for ruling out myogenic, peripheral nerve sheath, fibroblastic and fibrohistiocytic neoplasms with spindle cell features. An estimated 5% to 20% of thoracic SFTs may have malignant features. On the other hand, malignant extrathoracic tumors are rare. The diagnosis of malignancy is based on both clinical features and histologic findings. Surgery is recognized as the treatment of choice. The majority of SFTs are considered to be benign tumors; and the recommended management is complete surgical resection. In cases of positive resection margins patients should receive adjuvant radiation therapy. Factors that predispose to local recurrence in non-head and neck SFTs, are tumor diameter larger than 10 cm, presence of a malignant component, and positive surgical margins. Other authors also reported that the most important prognostic factor was resectability. In head and neck tumors, the high rate of positive margins reflects more likely the tumor location rather than its biologic features. Previous reports note that 13–37% of SFTs were associated with local recurrence or histological malignancy. A tumor recurrence has been described 31 years after surgical excision. Therefore, long-term follow-up is necessary even in cases with findings suggestive of benignity.

III. Conclusion

Solitary fibrous tumors of the head and neck region are extremely rare. The characteristic features of these tumors seen on CT or MRI, in conjunction with a benign slow-growing clinical behavior, may help in the diagnosis. Definitive diagnosis is usually made only after tumor resection. These tumors can be surgically excised, and patients who undergo complete surgical resection and do not have any malignant component, can expect a favorable outcome. However, patients with positive surgical margins or patients whose tumors have a malignant component may benefit from adjuvant postoperative radiation therapy.
