Abstract: Hydatid cystic disease is a common zoonotic infection in Indian subcontinent. However, in the following case, we report a rare presentation found in a young patient synchronously in paraspinal & intrahepatic location without intercommunication. Hydatid disease is to Echinococcus species commonly granulosus, sometimes multilocularis. The common locations of hydatid cyst are the liver (65% to 75%) and lungs (25%-30%). Hydatid disease rarely develops in some locations such as spleen, kidney, bones, heart, brain, peritoneum, myocardium and muscles (1-4%). A 25-year-old male presented with c/o backache on right & fullness in right paraspinal region. On clinical examination, he had a non-ballotable lump in right paraspinal region within intra muscular plane. CT abdomen (P+C) revealed well-defined hypodense non-enhancing cystic lesion in right lobe of liver with peripheral calcification with lesion of similar morphology in right paraspinal muscles. Exploration of right paraspinal region done. Cyst was beneath oblique & lattisimus dorsi, superficial to psoas muscle without invasion in it. Cyst opened multiple daughter cysts along with pus evacuated. Cyst excised in toto without spillage. Hydatid cyst is frequently asymptomatic, most prevalent in sheep and cattle-breeding areas. The cysts can not easily grow in muscles due to their contractility and lactic acid content. Surgery is the optimal treatment for hydatid cyst. Open cyst evacuation is indicated for gharbi types 4 & 5, posterior cysts, central cysts, more than 3 cysts, infected cysts, biliary communication, pulmonary communication, & peritoneal rupture. Alternative therapies with non-toxic scolicidal agents or combination chemotherapy has been advocated in the management of recurrence and high risk of contamination.

Keywords: Hydatid, paraspinal, surgery

I. Introduction

Hydatid disease is due to Echinococcus species commonly granulosus sometimes multilocularis. The common locations of hydatid cyst are the liver (65% to 75%) and lungs (25%-30%). Hydatid disease rarely develops in some locations such as spleen, kidney, bones, heart, brain, peritoneum, myocardium and muscles (1-4%). In our review of literature, concomitant paraspinal & intrahepatic hydatid is reported rarely.

II. Case Report

A 25-year-old male presented with c/o backache on right since 1 month & fullness in right paraspinal region. No h/o trauma, fever, burning micturition, pain in abdomen, weight loss, hematuria. On clinical examination, he had a non-ballotable lump in right paraspinal region of size 15x5x5 cm with ill-defined margins in intra muscular plane extending from posterior subcostal margin to iliac region with no overlying skin changes. No organomegaly. Blood investigations including liver function tests & kidney function tests were normal. Ultrasound examination revealed hepatomegaly with thick walled cystic lesion in right lobe of liver & in muscle plane in right renal angle region. CT abdomen (P+C) revealed well-defined hypodense non-enhancing cystic lesion of size 45x40 cm seen in right lobe of liver with peripheral calcification with lesion of similar morphology of size 14x5x3.6 cm in right paraspinal muscles with no intercommunication between them & no bone, spinal canal alteration or compression of right kidney. [Fig. 1, 2, 3]

Synchronous paraspinal and hepatic hydatid disease: a rare presentation

So our diagnosis of paraspinal hydatid cyst was confirmed. As patient was symptomatic only for paraspinal hydatid cyst only & size of hepatic cyst was small, exploration of right paraspinal region done after 21 day of antiscolicidal treatment. There was cyst of size 15x5x5 cm beneath oblique & lattisimus dorsi, superficial to psoas muscle without invasion in it [Fig.4]. Cyst opened multiple daughter cysts along with pus evacuated. Cyst excised in toto without rupture & spillage [Fig.5]. Negative suction drain was kept. Post operatively on day 3 drain was removed, stitches removed day 10 & discharged. Histopathology confirmed diagnosis.

III. Discussion

Hydatid disease is most prevalent in sheep- and cattle-breeding areas, where the first step in chain of transmission occurs.

The causative agent is introduced to the dog (the primary host) through the faeces of livestock. The minute larval form of E. granulosus lives in the small intestine of the dog species. The eggs are passed in the faeces of an infected dog and can be transferred to mammal (man – intermediate host) that ingests them. After ingestion, the
Synchronus paraspinal and hepatic hydatid disease: a rare presentation

Embryos are released from the eggs, that traverse the intestinal mucosa, and disseminate systemically via venous and lymphatic channels and develop into hydatid cysts in various body parts.

The cysts can not easily grow in muscles due to their contractility and lactic acid content. The wall of cyst in the muscle is formed by three layers, the inner germina, intermediate, and outer granulomatous adventitial layer. The most common skeletal sites include hip & thigh, shoulder & humerus regions.

Hydatid cyst is frequently asymptomatic [1]. The latent period of cyst development varies between 5 and 20 years [4, 5].

Serological tests are widely used to diagnose hydatid cyst. However, positive serological results do not confirm nor negative results exclude the disease [1, 6].

The imaging features of hydatid cysts are well described in the literature. US is a sensitive, safe, non-invasive method, it is the procedure of choice for the diagnosis of cysts with a “honeycomb” pattern (type 3), as observed in our patient. Gharbi’s classification provides morphological description on ultrasound.

Type 1- pure fluid collection, type 2- fluid collection with split wall (floating membrane), type 3- fluid collection with septa, type 4- heterogenous echographic pattern, type 5- reflecting thick walls.

As seen in our case the cyst fluid appears anechoic at US, yields an attenuation value of 3-30HU at CT. Calcifications in the cyst wall as in our case are best detected on CT scans. CT has the advantage of detecting smaller cysts when located outside the liver and sometimes differentiating parasitic from non-parasitic cysts & for follow-up studies during chemotherapy. Other diagnostic means such as fine needle aspiration should be avoided because of dangerous anaphylactic reactions [7].

Surgery is the optimal treatment for hydatid cyst.

Open cyst evacuation is indicated for Gharbi types 4 & 5, posterior cysts, central cysts, more than 3 cysts, large cysts, heavy calcification, infected cysts with above criteria, biliary communication, pulmonary communication & peritoneal rupture.

Laparoscopic evacuation is indicated in Gharbi type 1 or 2, anterior cysts, peripheral cysts, 1-3 cysts, small cysts, no or minimal calcification. Percystectomy is complete resection of cyst wall without entering the cyst cavity.

Alternative therapies with non-toxic scolocidal agents or combination chemotherapy using imidazole derivatives, particularly albendazol, has been advocated in the management of patients with recurrence and high risk of contamination [8].

IV. Conclusion

As hydatid cyst at paraspinal location mimics soft tissue tumor, psoas abscess; so high index of suspicion is necessary for diagnosis.
