Abstract: We consider an extension of the co-operative advertising model developed earlier by the authors. We consider a manufacturer-retailer channel co-ordination where the demand is modeled as a multiplicative effect of price and an additive sales response function. We develop both sequential and simultaneous moves non co-operative game structures where both retailer and manufacturer act simultaneously and independently and compare them through propositions. Finally we develop a cooperative model and discuss the optimality of pareto efficient scheme.

Keywords: Cooperative advertising, Game theory, Nash equilibrium, Stackelberg equilibrium, Supply chain coordination

I. Introduction

A relationship between manufacturer and retailer in which retailer gets some part of amount for local advertising from manufacturer is vertical co-op advertising. Generally vertical co-op advertising has focused on a relationship between manufacturer and retailer where manufacturer is a leader and retailer is a follower. So there is a chance that manufacturer dominates the retailer. In recent market retailer has equal or more power then manufacturer (Buzzellet al., 1990 and Fulop, 1988). To avoid distraction of multiple products, multiple manufacturers and retailers we investigate single manufacturer and a single retailer case and after the development of methodology we generalize the model for multiple manufacturer and retailers. In next section, we develop the classic relationship between manufacturer and retailer named “leader-follower” two stage games. An equilibrium of this game is called the stackelberg equilibrium. In a sequential move game the manufacturer as a leader specifies the brand name investments and the retailer as a follower then decides on the local advertising level. In the stackelberg equilibrium, if the ratio of the manufacturer and retailer’s marginal profits is relatively high then manufacturer offers a positive amount for advertising to retailer but if marginal profit ratio is low then manufacturer offers zero amount of allowance to retailer. Solanki and Gor (2013) developed two game theoretic models; a cooperative model and a non cooperative model in a stackelberg game framework. This paper follows some of the part with a different sales response function.

In next section we consider a simultaneous move game where the manufacturer and the retailer independently maximize their individual profits. Its equilibrium is called Nash equilibrium.

The manufacturer’s brand name investment is higher at Nash equilibrium then at stackelberg equilibrium. If the profits ratio of the retailer and the manufacturer is relatively low, then the local advertising expenditure is lower at Nash equilibrium than at stackelberg equilibrium; otherwise it is higher at Nash equilibrium than at stackelberg equilibrium.

The system profit is higher with cooperation then with non-cooperation and maximized for every Pareto efficient co op advertising scheme, but not for any other schemes. The system profit is higher at any Pareto efficient scheme than at both noncooperative equilibriums. Also, if the marginal profits ratio of the retailer and manufacturer is relatively high, then the manufacturer’s brand name investment is higher at any Pareto efficient scheme than at both noncooperative equilibriums; otherwise the manufacturer’s brand name investment at any Pareto efficient scheme is higher than at Stackelberg equilibrium and is lower than at Nash equilibrium. The local advertising expenditure is higher at any Pareto efficient scheme than at both noncooperative equilibriums.

All proofs of results are given in Appendix.

Assumptions

We assume that one manufacturer sells through one retailer i.e. Single-manufacturer-single retailer channel in which the retailer sells only the manufacturer’s brand within the product class. This ensures analytical tractability of solutions. It can be further extended thereafter. Co operative advertising is used to attract customers at the time of actual purchase. Potential customers can be aware about the product by manufacturer’s national advertising and local advertising by retailer bring potential customers to the stage of desire and action. It gives customers the reason such as low price and high quality to buy and also aware about

A Single period co operative advertising model where demand is dependent on price and an ....

when and where to obtain the product. Though manufacturer and retailer’s advertising performance are different but it creates positive effect on product sale.

Notations:
p: retailer’s selling (retail) price
w: manufacturer’s selling (wholesale) price
a: retailer’s local advertising expenditure, \( a \geq 0 \)
A: manufacturer’s national advertising expenditure, \( A \geq 0 \)
t: the manufacturer participation rate, the percentage that the manufacturer agrees to pay the retailer to subsidize the local advertising cost

Following Kuehn, 1962; Thompson and Teng, 1984; Jorgensen and Zaccour, 1999, 2003, multiplicative effect of the price (using an appropriate function) and advertising (using a sale response function) is used to model the consumer demand as

\[
D(p, a, A) = g(p) \cdot h(a, A) \tag{1}
\]

Where \( g(p) \) reflects the impact of the retail price on the demand and \( h(a, A) \), the sales response function reflects the impact of the advertising expenditures on the demand. Following the well known structure in demand literature, \( g(p) \) is a linearly decreasing function of \( p \) and is specifically taken as

\[
g(p) = \gamma_0 - \gamma_1 p \tag{2}
\]

where \( \gamma_0 \gg \gamma_1 \) and to ensure \( g(p) > 0 \), we need to restrict \( p < \left( \frac{\gamma_0}{\gamma_1} \right) \)

Modeling the sale response function: Simon and Arndt (1980) concluded that diminishing returns characterize the shape of the advertising-sales response function. Similar approaches of relating demand and advertising expenditure were used in Kim and Staelin (1999) and Karray and Zaccour (2006). Assuming that both the types of advertising efforts; national and local, could influence sales and that their effects should be assessed separately (Jorgensen et al., 2000; Huang et al., 2002), we model advertising effects on consumer demand as

\[
h(a, A) = k_r \log a + k_m \log A \tag{3}
\]

where \( k_r, k_m \) are positive constants reflecting the efficacy of each type of advertising in generating sales. The above equation captures both types of advertising effects which usually are not substitutes. The demand \( h \) is an increasing and concave function with respect to \( a \) and \( A \), and has the property that is consistent with the commonly observed “advertising saturation effect”, i.e., additional advertising spending generates continuously diminishing returns.

\[
D(p, a, A) = (\gamma_0 - \gamma_1 p) (k_r \log a + k_m \log A) \tag{4}
\]

The manufacturer’s, retailer’s and system’s expected profit functions are as follows.

\[
\pi_m = w (\gamma_0 - p \gamma_1) (k_r \log a + k_m \log A) - ta - A \tag{5}
\]
\[
\pi_r = (p - w) (\gamma_0 - p \gamma_1) (k_r \log a + k_m \log A) - (1 - t)a \tag{6}
\]
\[
\pi_{m+r} = p (\gamma_0 - p \gamma_1) (k_r \log a + k_m \log A) - a - A \tag{7}
\]

II. Stackelberg Equilibrium

We model the relationship between the manufacturer and retailer in which manufacturer is a leader and retailer a follower. It is a sequential noncooperative game.

Since the \( \pi_r \) is a concave function we can set its first derivative with respect to \( a \) to be zero.

\[
\frac{\partial \pi_r}{\partial a} = (p - w) (\gamma_0 - p \gamma_1) \frac{k_r}{a} - (1 - t) = 0 \tag{8}
\]

Then, we have

\[
a = \frac{(p-w)(\gamma_0-p\gamma_1)k_r}{(1-t)} \tag{9}
\]

Equation (9) shows positive change in manufacturer’s co–op advertising reimbursement policy and brand name investments. We can observe that

\[
\frac{\partial a}{\partial t} = \frac{(p-w)(\gamma_0-p\gamma_1)k_r}{(1-t)^2} > 0 \tag{10}
\]
\[
\frac{\partial a}{\partial t} = 0
\]  
(11)

Equation (10) shows that the more the manufacturer is willing to share the cost of local advertising, the more the retailer will spend on the local advertising.

Also, the optimal value of A and t are determined by maximizing the manufacturer’s profit subject to the constraint imposed by eq. (9). The manufacturer’s problem is as follow.

\[
\max_{A,t} \pi_m = w(\gamma_0 - p\gamma_1)(k_r \log a + k_m \log A) - ta - A
\]  
(12)

s.t. \(0 \leq t \leq A \geq 0\),

where, \(a = \frac{(w-p)(\gamma_0 - p\gamma_1)k_r}{(1-t)}\)

Substituting the value of a in to (12), we get

\[
\max_{A,t} \pi_m = w(\gamma_0 - p\gamma_1)\left(k_r \log \left(\frac{(w-p)(\gamma_0 - p\gamma_1)k_r}{(1-t)}\right) + k_m \log A\right) - t \left(\frac{(w-p)(\gamma_0 - p\gamma_1)k_r}{(1-t)}\right) - A
\]  
(13)

s.t. \(0 \leq t \leq A \geq 0\).

Solving equation (13) for \(t\) and \(A\) and substituting then in eq. (9) we get unique equilibrium point, \((a^*, t^*, A^*)\) of the two – stage game as follows.

\[
a^* = \left(\frac{w(\gamma_0 - p\gamma_1)k_r}{(2w-p)}, \text{ otherwise}\right)
\]  
(14)

\[
t^* = \begin{cases} \frac{2w-p}{w} & , \quad 2w > p \\ 0 & , \quad \text{otherwise} \end{cases}
\]  
(15)

\[
A^* = (w(\gamma_0 - p\gamma_1)k_m)
\]  
(16)

We have following important results regarding manufacturer – retailer local advertising sharing rule.

**Proposition 1.** If \(2w > p\), then (i) the manufacturer offers positive advertising allowance to the retailer, otherwise he will offer nothing, and (ii) the manufacturer’s advertising allowance for the retailer is positively and negatively correlated to changes in the manufacturer’s marginal profit and retailer’s marginal profit, respectively.

### III. Nash Equilibrium

In above section, we deal with two – stage noncooperative game structure where manufacturer as a leader holds extreme power and has complete control over the behavior of the retailer. It is the relationship of employer and employee.

Let \(\max_{A,t} \pi_m = w(\gamma_0 - p\gamma_1)(k_r \log a + k_m \log A) - ta - A\) and

\[
\max_{A,t} \pi_r = (p-w)(\gamma_0 - p\gamma_1)(k_r \log a + k_m \log A) - (1-t)a
\]

Solving by taking first derivative of \(\pi_m\) with respect to \(A\) and \(\pi_r\) with respect to a equal to zero and substituting \(t = 0\) we get,

\[
A^* = (w(\gamma_0 - p\gamma_1)k_m)
\]

\[
a^* = \left(\frac{(p-w)(\gamma_0 - p\gamma_1)k_r}{(1-t)}\right)
\]

\[
t^* = 0
\]

In recent market studies we found that now retailers have increased their power relative to manufacturers. In this section we assume a symmetric relationship between the manufacturer and the retailer. It is assumed that the manufacturer and the retailer simultaneously and noncooperatively maximize their profits with respect to any possible strategies set by other member.

The following two propositions give the detailed comparisons among two different noncooperative game structures.

**Proposition 2.** i) The manufacturer always prefers the leader-follower structure rather than the simultaneous move structure. (ii) If \(p \geq 2w\), the retailer prefers the simultaneous move game structure; otherwise he prefers the leader – follower game structure.

**Proposition 3.** (i) The manufacturer’s brand name investment is same at Nash and Stackelberg. (ii) If \(p \geq 2w\), then the retailer’s local advertising expenditure is higher at Nash than at Stackelberg; otherwise, it is lower at Nash than at Stackelberg. (iii) The manufacturer’s advertising allowance for the retailer is zero.

### IV. An Efficiency Co – Op Advertising Model

We discussed two noncooperative game structures above for a sequential move and a simultaneous move. The manufacturer who can promote its brand by national advertisement may not know about local market and retailer’s advertising behavior. So, the retailer knows how much if any, of the manufacturer’s money is spent on local advertising. But many retailers use the manufacturer’s money and co operative advertising programs for their own purposes and reduce their dependence on the manufacturers. Co – op advertising should not be used as a offer from a manufacturer to pay part of a retailer’s local advertising costs on the product, but should be used as a tool to enhance manufacturer’s brand name and retailer’s store reputation.
Appendix A. Proof of results

Proof of Proposition 2

(i) Since the retailer’s response to every strategy of the manufacturer is unique in the two-stage game, the leader’s payoff will not be less than that at Nash equilibrium. Therefore, \( \pi_m^{**} \leq \pi_m^* \).

(ii) \( \pi_r^{**} - \pi_r^* = (p - w) (y_0 - p y_f) k_r \log \left( \frac{p - w}{w} \right) \geq 0 \) if \( p \geq 2w \)

\[ < 0 \text{ otherwise} \]

Proof of Proposition 3

(i) \( A^{**} - A^* = (w (y_0 - p y_f) k_m) - (w (y_0 - p y_f) k_m) = 0 \)

(ii) \( a^{**} - a^* = (p - w) (y_0 - p y_f) k_r - w (y_0 - p y_f) k_r \)

\[ = ( (y_0 - p y_f) k_r) \{ p - 2w \} \geq 0 \text{ if } p \geq 2w \]

\[ < 0 \text{ otherwise} \]

(ii) \( t^{**} = 0 \)

Proof of Proposition 4

Since \( \nabla \pi_m(a, t, A) = \left( \begin{array}{c} \frac{\partial \pi_m}{\partial a} \\ \frac{\partial \pi_m}{\partial t} \\ \frac{\partial \pi_m}{\partial A} \end{array} \right) \)

\[ \nabla \pi_r(a, t, A) = \left( \begin{array}{c} \frac{\partial \pi_r}{\partial a} \\ \frac{\partial \pi_r}{\partial t} \\ \frac{\partial \pi_r}{\partial A} \end{array} \right) \]

Utilizing eq. (17) we can get \( \mu = 1, \alpha^* \) and \( A^* \) in eq. (18) and with \( t \) between 0 and 1.

Proof of Proposition 5

Let the joint system maximization problem be as follows:

\[ \tilde{\pi} = \max_{a, A, t} \pi_m + \pi_r = \int (y_0 - p y_f) (k_r \log a + k_m \log A) - a - A \]

s.t. \( 0 \leq t \leq 1, A \geq 0, a \geq 0 \)

It does not contain the variable \( t \), any value of \( t \) between 0 and 1 can be component for any optimal solution of (19).

Taking the first derivatives of \( \pi \) with respect to \( a \) and \( A \), and setting them to zero, we have

\( \alpha^* = (p (y_0 - p y_f) k_r) \)

and

\( A^* = (p (y_0 - p y_f) k_m) \)

Therefore, \( (\alpha^*, t, A^*) \) for any \( t \) in \([0, 1]\) is an optimal solution of (19).
