Abstract: Lymphatic filariasis is a mosquito-borne parasitic disease and an important cause of chronic morbidity in tropical countries. Detailed observations of lymphatic filariasis were conducted in Narasannapeta urban village of Srikakulam district in Andhra pradesh. Out of the 1660 persons examined, 8.1% were found asymptomatic but microfilaraemic. Morbidity pattern due to filarial infection showed an increase with advancement of age and significantly high in males as compared to female. Acute and chronic filarial disease was observed as 0.3% and 7% respectively. Microfilaria was found in 8.1% of acute and 9.5% of chronic filarial cases. The Mf rate was found to be 8.7% in males and 7.9% in females respectively. The parasite species was identified as W. bancrofti. Each household and predomestic area was searched for mosquito fauna at night. The filariasis cases detected in the study were treated with 12 days course of DEC 6mg/kg body weight. Health authorities should strictly exercise powers on all developmental projects to act in such a way that does not create mosquitoogenic conditions.

Keywords: Lymphatic filariasis, Microfilariaemia, Morbidity, chronic, mosquito- genic, Narasannapeta.

I. Introduction

The nematode microfilaria (Wuchereria bancrofti) affects more than 115 million people worldwide. Filariasis or Elephantiasis is a major public health and socio-economic problem in India, approximately 420 million people reside in endemic areas and 48.11 millions are infected (Michael et al, 1996). Filariasis is caused by W. bancrofti, B. malayi and B. timori and it spreads by the bite of an infected Culex mosquito. Culex quinquefasciatus (previously known as Culex fatigans) is the main vector for its spread. However, other vectors may also be responsible like Anopheles, Mansonia etc. The World Health Organization (WHO) has identified filariasis as second leading cause of permanent and long-term disability next only to mood affecting disorder (Ramaiah et al, 2002). In India, filariasis has been recognized as disease of National importance because of continuous spread of disease and protracted suffering and disability caused in the affected population. India contributes to 40% cases of bancroftian filariasis in the global scenario (http://www.who.int). Filariasis is one of the major parasitic infections of mankind, which is widely spread throughout the tropical and subtropical places. Filariasis that are caused by threat like filarial nematode worms and transmitted by mosquitoes. They occur in the poor in underdeveloped regions of South America, Central Africa, Asia, the Pacific Islands, and Caribbean (WHO-2002).

The disease has a major socio-economic impact. National Filaria Control Programme (NFCP) was launched in 1955. Initially the programme was limited to urban population but after 1994 the programme was extended to include rural population also. From 2003-04, the programme became a part of National Vector Borne Disease Control Programme (NVBDCP) and it aimed to eliminate lymphatic filariasis by 2015 under National Health Policy 2002. Elephantiasis is a more intense in people who don’t live in this area, because many native people have built up some immunity. Symptoms of elephantiasis include fever, shaking chills. Sweating, headaches, vomiting and pain. Enlarge lymph nodes, swelling of the affected area, skin ulcers, bone and joint pain, tiredness, and red streaks along the arm or leg also may occur. Abscesses can from in lymph nodes or in the lymphatic vessels. They may appear at the surface of the skin as well as long-term infection with lymphatic filariasis can lead to lymph edema, hydrocele in the scrotum, and elephantiasis of the legs, scrotum, arms, penis, breasts, and vulvae. Most cases of elephantiasis are caused by two species namely Wuchereria bancrofti and Brugia malayi are prevalent in India and former contributes 99.4% problem in the country. In mankind the microfilaria (mf) exhibit nocturnal periodicity, necessitating night blood surveys between 12 am to 2 am.
midnight to detect microfilaria carriers. In endemic regions of lymphatic filariasis, humans exhibit a broad range of responses towards infection. These responses are classically divided into following groups.

II. Material And Methods

This study was conducted in Narasannapeta villages of Srikakulam district of Andhra Pradesh. All individuals of the study area were screened for mf and clinical sign and symptom of filariasis. Support of some local headmen and influential persons was also solicited before start of work to minimize refusal and smooth functioning. Villagers were requested to consent and for cooperation. A central place (Club house/school) was selected for clinical and parasitological examination. The details with regard to age, sex, migration status as well as the filarial clinical profile of the person examined, were recorded in predesigned proformae. Information about mosquito breeding sites, water sources, plantation, drainage system were also recorded in proformae. Conventional finger prick technique was used to collect 20 cm3 blood from each person between 8-12 PM. The blood slides thus collected were dehaemoglobinised, fixed with 2% acidalcohol and later stained with Giemsa 1:20 dilution and examined for microfilaria in thick blood slide.

Thin blood smear was also prepared and stained with leishman's stain were examined under microscope for hematological parameters. Confirmatory diagnosis presents one of the most difficult problems in parasitology. Diagnosis is based on the demonstration of parasite which includes. Conventional Night blood smears examination.

Microscopic examination of 20 mm stained blood film was the best diagnostic technique for the field work. Observation of slides under Binocular microscopic examination and recorded infected and no infected slides i.e. date of blood sample collected and date of blood sample examined and number of parasites. Further to develop base line entomological data, a trained insect collector collected the adult mosquitoes between 8 PM to 12 PM using torchlight and aspirator tube. All the mosquitoes thus collected were identified and dissected to detect the developmental stage of filarial parasites.

III. Observation

1. In the observation prevalence of W.bancrofti and B.malayi was examined during (July 2014 to June 2015) in the blood samples collected from the positive filarial cases (In the study area of Narasannapeta population). 4644 blood samples were collected from fever cases and smear were prepare out of 4644 fever cases, 133 filarial W.bancrofti positive cases were found and there was no prevalence of B.malayi filarial cases. No filarial positive cases were found in age group of 2-5 years and 6-14 years in all the 24 wards of study area. In the age group of 15 years and above, 133 W.bancrofti positive cases (Male 57;Female 76).

In the present study before treatment with DEC, there is high level of IgA, IgG and IgM in occult, acute and chronic patients. Similarly after treatment with DEC, there is normal level of IgA, IgG and IgM in acute and occult patients and high level of IgA, IgG and IgM in chronic patients. There observations are comparable to that of who found extreme levels of serum IgE and high titres of antifilarial IgG, IgE in patients of symptomatic microfilaraemia.

In the present study, before treatment with DEC, the occult, acute and chronic patients showed low count of CD3, normal count of CD4 and low count of CD8. Similarly after treatment with DEC, CD3, CD4 and CD8 cell count in normal range.

- In the present survey microfilaria (mf) rate and mean mf density was in the male mf rate 8.7%; diseases rate 11.3%; and in the female mf rate 7.9%; diseases rate 5.4%.
- Total mf rate (male +female) 8.4% and disease rate 8.5%, mf density was found in 15 years and above age group.
- The sample of clinical manifestation shown by the patients forms the basis to separate in to three groups as occult, acute and chronic. Filarial patients showed low lymphocytes count, normal range of CD4 cells and low number of CD8 cells.
- The CD4:CD8 ratio was found to be normal among all the selected filarial patients before and after treatment with DEC observations.

IV. Results

Filarial infection was assessed for each respondent by examining the microfilaria (MF) from the collected blood sample. About 35% of study population was illiterate and 15% of the households got cattle shed inside their houses and water logging was found in nearly 28% houses. The nearest Primary Health Center (PHC) was located on the main road meanwhile Private Hospital facilities were to be availed.

The total number of examined 1660:, 860 were males and 800 females examined clinico parasitologically. History of at least one attack of filarial adenolymphangitis or adenolymphadenitis during last year was reported in 30% of acute and 65% of chronic filarial disease cases. It was observed that 92% examined population neither manifested any evidence of clinical filarial diseases nor infection (asymptomatic microfilar-

...emic) i.e. thus normal healthy people and 7.9% had definite evidence of filariasis infection in their blood. Out of which microfilaraemia was demonstrated amongst 5.4% of screened population but no clinical sign and symptoms (Asymptomatic microfilar- aemic) were seen. Acute and chronic filarial disease was observed in 0.3% and 0.7% respectively, only 0.15% were both symptomatic and microfilaraemic. The disease in male was significantly higher as compared to females. Multiple adenolymphangitis was reported by 12% of cases with chronic disease. Out of 123 diseased, hydrocele was reported in 46 .The manifestation of hydrocele without any history or other evidence of filariasis was seen amongst 0.12%. Limb edema was observed in 41% of cases predominantly affecting lower limb. 

The Mf rate was (8.7%) slightly higher in males than 7.9% in females, it was (4.9%) in age group 0-14 significantly lower than (13.3%) in the age group of 20-60 with a peak prevalence at the age group of 15-19 and the same in male and female. The prevalence of disease was not observed in younger ages (14 years) but then increased with age and reached the maximum at 25-29 years for both males and females and then declined at older ages. The parasite species was identified as W. bancrofti.

V. Conclusion And Discussion

Based on the reports of health department, Govt. of Andhra Pradesh it is understood that, Lymphatic filariasis is one of the important public health problemvin A.P. Though the programme for control of disease was started in 1955-1956, it met with limited success. A study in Dibrugarh (Assam) reported Mf rate of 7.6% in males and 5.9% in females slightly lower than our study finding. The entomological data indicates that W. bancrofti was the main vector in this area with 12% infection rate and 6.9% infectivity suggesting active transmission in the area and manifold higher than reported from Pondicherry but lower than the observed vector infectivity of 11.3 % in Bhubaneswar. Thus it can be inferred from present study that indication of active filarial transmission.

About 8.4% population was asymptomatic microfilaraemic coincides with study in Varanasi. The morbidity amongst male was significantly higher than in female that accounted for 32.5% of hydroceles. It had already documented those factors like migration of mf carriers, steady deterioration of urban eco-system affecting the environment thereby Promoting mosquitogetic conditions, poor and disorganized mosquito abatement measures favor transmission of filariasis. Here again high vector densities, lower socioeconomic status, etc. may be suggested to be the reasons for establishing the infection, as noted. 80% people do not take it as a serious disease and not bothered about this disease, only 19% accepted DDT as a control measure.

Irregular DDT spraying was documented by earlier conducted studies on Kala-azar-one of the major public health problem of Bihar. The State health department observed filiariasis week under FCP in which blood was collected for Mf and drug was distributed if found ill. If this situation is allowed to be continued without appropriate intervention the morbidity may increasefurther However, recent growing support for mass chemotherapy programmer provides hope that the burden of lymphatic filariasis can be reduced, if not eliminated, as happened at Tahiti and Further health authorities should strictly exercise powers on all developmental projects to act in such a way that does not create mosquitogetic conditions. This may be helpful for reduction of the transmission and improve health conditions of the population of Narasannapeta.
